Abstract

The tectonic and geodynamic setting of the southern Central Andean convergent margin changed significantly between the Late Cretaceous and the Late Miocene, influencing magmatic activity and its geochemical composition. Here we investigate how these changes, which include changing slab-dip angle and convergence angles and rates, have influenced the contamination of the arc magmas with crustal material. Whole rock geochemical data for a suite of Late Cretaceous to Late Miocene arc rocks from the Pampean flat-slab segment (29 – 31 °S) of the southern Central Andes is presented alongside petrographic observations and high resolution age dating. *In-situ* U-Pb dating of magmatic zircon,

combined with Ar-Ar dating of plagioclase, has led to an improved regional stratigraphy and provides an accurate temporal constraint for the geochemical data.

A generally higher content of incompatible trace elements (e.g. Nb/Zr ratios from 0.019 to 0.083 and Nb/Yb from 1.5 to 16.4) is observed between the Late Cretaceous (~72 Ma), when the southern Central Andean margin is suggested to have been in extension, and the Miocene when the thickness of the continental crust increased and the angle of the subducting Nazca plate shallowed. Trace and rare earth element compositions obtained for the Late Cretaceous to Late Eocene arc magmatic rocks from the Principal Cordillera of Chile, combined with a lack of zircon inheritance, suggests limited assimilation of the overlying continental crust by arc magmas derived from the mantle wedge. A general increase in incompatible, fluid- mobile/immobile (e.g., Ba/Nb) and fluid- immobile/immobile (e.g., Nb/Zr) trace element ratios is attributed to the influence of the subducting slab on the melt source region and/or the influx of asthenospheric mantle.

The Late Oligocene (~26 Ma) to Early Miocene (~17 Ma), and Late Miocene (~6 Ma) arc magmatic rocks present in the Frontal Cordillera show evidence for the bulk assimilation of the Permian – Triassic (P-T) basement, both on the basis of their trace and rare earth element compositions and the presence of P-T inherited zircon cores. Crustal reworking is also identified in the Argentinean Precordillera; Late Miocene (12 – 9 Ma) arc magmatic rocks display distinct trace element signatures (specifically low Th, U and REE concentrations) and contain inherited zircon cores with Proterozoic and P-T ages, suggesting the assimilation of both the P-T basement and a Grenville-aged basement. We conclude that changing geodynamics play an important role in determining the geochemical evolution of

magmatic rocks at convergent margins and should be given due consideration when evaluating the petrogenesis of arc magmas.

Keywords – Central Andes, geochronology, arc magma petrogenesis, crustal contamination, geodynamics

1. Introduction

Subduction zones are the principal sites for the production of new continental crust through the production of arc magmas. Determining the relative contributions to arc magmas from the mantle, subducting components (e.g., sediments, oceanic crust) and pre-existing crust, are key to quantifying rates of crustal growth and recycling over time. Crustal material can either be incorporated into arc magmas in the melt source region, due to the subduction of sediments/subduction erosion of overriding lithosphere, and/or due to the assimilation of the overlying crust as arc magmas migrate towards the surface. The Andean margin has been an important site for continental crust production throughout the Cenozoic and is a type locality of an ocean-continent convergent margin.

The recycling of crustal material to Andean arc magmas has been long identified, however the mode of recycling is widely debated. Although most authors agree that there is an increase in the contributions to Central Andean arc magmas from crustal derived material over the course of the Cenozoic, the origin (i.e., subducted crustal material or the overlying Andean crust) of these crustal signatures remains unresolved. The contamination of the melt source region with subducted sediments (e.g., Kilian and Behrmann, 2003; Lucassen et al., 2010; Sigmarsson et al., 1990), crustal material from subduction erosion (e.g., Goss et al., 2013; Kay et al., 2005; Stern, 1991), melts derived from the subducting oceanic plate (e.g., Reich et al., 2003; Stern and Kilian, 1996), as well as the contamination of arc magmas

during ascent through the continental crust (e.g., Davidson et al., 1991; Hildreth and Moorbath, 1988; James, 1982; Wörner et al., 1992), have all previously been invoked to explain the petrological and geochemical characteristics of arc magmatic rocks from the Andean margin.

The Andean margin is segmented along its length, with different segments being influenced by different tectonic regimes and geodynamic settings (e.g., Jordan et al., 1983; Pilger, 1981). The geodynamic setting of the southern Central Andean margin has changed significantly over the course of the Cenozoic. Specifically, the angle at which the Nazca plate subducted beneath the South American continent shallowed during the Miocene (e.g., Cahill and Isacks, 1992; Yañez et al., 2002; Yañez et al., 2001). This resulted in the margin developing from the extensional regime in existence during the Late Cretaceous (~75 Ma) to a highly compressive regime during the latter part of the Miocene (Jordan et al., 1983). Consequently the thickness of the continental crust increased from ~30 km to >50 km over the latter part of the Cenozoic (Allmendinger et al., 1990; Chulick et al., 2013; Fromm et al., 2004; McGlashan et al., 2008).

The shallowing of the subducting Nazca plate has been linked with the subduction of the Juan Fernandez Ridge (JFR), a hotspot-derived seamount chain which may have undergone significant hydration and serpentinitisation (e.g., Gutscher et al., 2000b; Jones et al., 2014; Kay and Mpodozis, 2002; Kopp et al., 2004; Pilger, 1981; Yañez et al., 2002; Yañez et al., 2001). The intersection and subduction of the JFR has also been associated with increased levels of subduction erosion of the fore-arc (e.g., Stern, 1991; Stern and Skewes, 1995; von Huene et al., 1997) and is thought to act as a barrier to sediment transport and the

accumulation of sediments in the Chilean trench north of ~33°S (Völker et al., 2013; von Huene et al., 1997).

These changes in tectonic and geodynamic setting over time make the southern Central Andes an interesting location at which to investigate changes in the contamination of arc magmas with crustal derived material. Previous studies into the petrogenesis of Cenozoic arc magmas in this region have primarily utilised whole rock geochemistry (e.g., Bissig et al., 2003; Kay and Abbruzzi, 1996; Kay et al., 1991; Litvak and Poma, 2010; Litvak et al., 2007; Parada, 1990; Winocur et al., 2015) and have tended to focus on narrow geological timeframes or geographical areas. In this study a variety of geochronological and geochemical techniques have been applied to both plutonic and volcanic arc rocks, which have been emplaced and erupted over a wide time frame (~73 – 6 Ma) and over a wide across-arc extent, from the Principal Cordillera of Chile (-70.8 °W) to the Argentinean Precordillera (-69.1 °W), allowing a more complete picture to be established.

A comprehensive new major, trace and rare earth element data set is presented alongside the results of high resolution U-Pb and Ar-Ar age dating. Prior to this study the majority of the age information available for the southern Central Andean arc stratigraphy has been derived from K-Ar dating (e.g., Limarino et al., 1999; Litvak and Page, 2002; Mpodozis and Cornejo, 1988; Nasi et al., 1990; Pineda and Calderón, 2008; Pineda and Emparan, 2006), combined with some Ar-Ar dating (Bissig et al., 2001) and limited U-Pb dating (Martin et al., 1997). Due to the variable effects of hydrothermal alteration on the arc magmatic rocks (e.g., Bissig et al., 2001; Litvak et al., 2007; Makshev et al., 1984) some of the K-Ar ages have been found to be unreliable (Winocur et al., 2015). On this basis, this study conducted high resolution *in-situ* U-Pb dating of magmatic zircon and Ar-Ar dating of plagioclase in order to

improve the regional stratigraphy and to provide an accurate temporal constraint for the geochemical data. In addition, *in-situ* U-Pb dating has the potential to reveal inherited zircon cores and therefore can be used to identify the age of the continental crust being assimilated (e.g., Beard et al., 2005). Finally, the results obtained have been used to investigate the growth and evolution of the Andean continental crust and to refine geodynamic models of the evolution of the Pampean flat-slab segment.

2. The geological and geodynamic setting

The study area is located within the Pampean (Chilean) flat-slab segment (between 29 – 31 °S) of the southern Central Andes and spans the Principal Cordillera, Frontal Cordillera and Precordillera of Chile and Argentina (Fig. 1). Subduction of oceanic crust beneath the South American continent has been active since the Jurassic and has produced a series of volcanic arcs (e.g., Charrier et al., 2007; Ramos et al., 2002; Stern, 2004). From the Cretaceous through to the Late Oligocene the southern Central Andes is considered to have been in extension (e.g., Charrier et al., 2007 and references therein). At ~25 Ma the oceanic Farallón plate divided into the Nazca and Cocos plates (Lonsdale, 2005). This caused an increase in convergence rates (from ~8 cm/yr to ~15 cm/yr) and a change from oblique (NE-SW) to orthogonal (ENE-WSW) convergence (Pardo Casas and Molnar, 1987; Somoza, 1998a; Somoza and Ghidella, 2012). The westward migration of the South American plate is also thought to have been initiated after ~30 Ma (Silver et al., 1998). After this time the Andean margin became more compressional and the reconfiguration of the subducting oceanic plates has been linked to a period of major uplift, increased magmatic activity, and a broadening and eastward migration of the magmatic arc (Pilger, 1984). Increased convergence rates (~15 cm/yr) are thought to have been sustained up until ~20 Ma,

followed by a gradual decline to present day values (~7cm/yr) (Pilger, 1984; Somoza and Ghidella, 2012).

There is currently no active volcanism in the Pampean flat-slab segment due to the low angle at which the oceanic Nazca plate subducts beneath the South American continent (e.g., Cahill and Isacks, 1992). The JFR began intersecting the Andean continental margin during the early Miocene (~18Ma at ~30 °S) and is thought to have led to the shallowing of the subduction angle (Gutscher et al., 2000b; Jones et al., 2014; Kirby et al., 1996; Nur and Ben-Avraham, 1981; Pilger, 1981, 1984; Yañez et al., 2002; Yañez et al., 2001). This shallowing led to a broadening and eastward migration of the magmatic arc, a reduction in magma volume, and the eventual cessation of arc magmatism in the late Miocene (~6 Ma) (Bissig et al., 2001; Kay et al., 1987; Litvak et al., 2007; Ramos et al., 1989).

3. Cenozoic arc magmatism and stratigraphy

In the southern Central Andes the Cenozoic plutonic and volcanic arc rocks occur as north-south trending belts which lie to the east of the Coastal Batholith, which is primarily late Paleozoic to early Cretaceous in age. The older, more continuous western belt was intruded in the Paleocene - Eocene and the younger more eastern belt is of Oligocene-Miocene age, demonstrating an eastward migration of magmatism with time (Parada et al., 2007) (Fig. 1). There is a geographical gap between the two belts which corresponds with a widespread lull in magmatic activity between ~39 – 26 Ma (Parada et al., 2007; Parada et al., 1988). In order to provide a context for the geochemical data, the Cenozoic arc stratigraphy for the southern Central Andes is outlined below and in Figure 2.

The Paleocene - Eocene belt is located in the Chilean Principal Cordillera (Fig. 1) and is primarily composed of epizonal plutons which have been assembled into the Cogotí

165 Supergroup (Parada et al., 1988). Granitoids of the Cogotí Supergroup have K-Ar ages
166 between 67 ± 2 Ma and 38 ± 1 Ma (Parada et al., 1988 and references therein). However,
167 Parada et al. (1988) note there is evidence of partial Ar loss, suggesting the Cogotí
168 Supergroup is likely to be Late Cretaceous to Paleocene in age. Coeval to the Cogotí
169 Supergroup is the extrusive Los Elquinos Formation (69.8 ± 0.9 Ma to 57.6 ± 2.5 Ma (Pineda
170 and Emparan, 2006)) which consists of basaltic to rhyolitic lavas, tuffs and breccias (Charrier
171 et al., 2007). During the Paleocene a number of calderas, including the Tierras Blancas
172 Caldera (Emparan and Pineda, 1999), also formed along the margin between 26 and 30 °S
173 (Charrier et al., 2007). To the east of the volcanic arc, mafic, intra-plate volcanism was
174 concurrent with the emplacement of the Cogotí Supergroup (Litvak and Poma, 2010). The
175 Río Frío Basalts were erupted in what is now the Argentinean Frontal Cordillera and have
176 been K-Ar dated at 55.9 ± 1.9 Ma (Litvak and Page, 2002).

177 A general reduction in magmatic activity has been identified between ~39 and 26 Ma in the
178 southern Central Andes (Parada et al., 1988), however, some arc magmatism continued
179 during this time interval. The Bocatoma Unit has been dated as Eocene to Early Oligocene
180 with reported Ar-Ar and K-Ar ages ranging between 39.5 and 30 ± 1.9 Ma (Bissig et al., 2001;
181 Martin et al., 1995; Mpodozis and Cornejo, 1988; Nasi et al., 1990). This primarily intrusive
182 unit consists of fine grained to coarsely porphyritic diorites and granodiorites, and some
183 andesitic porphyries (Bissig et al., 2001; Maksaev et al., 1984). A number of dacitic and
184 rhyolitic ignimbrites and lava flows located in the Valle del Cura region (Frontal Cordillera,
185 Argentina) have been K-Ar dated between 44 ± 2 and 34 ± 1 Ma and have been assigned to
186 the Valle del Cura Formation (Limarino et al., 1999; Litvak and Poma, 2005). However, it has
187 recently been suggested that these Eocene to early Oligocene K-Ar ages may be unreliable

due to the high levels of hydrothermal alteration evident in these units and new Ar-Ar dating suggests these volcanic sequences are Oligocene to Early Miocene in age (Winocur et al., 2015).

Following the break-up of the Farallón plate and reconfiguration of the margin at ~25 Ma (Lonsdale, 2005), the extensive Doña Ana Group was erupted at and near the arc front, spanning either side of the current Chilean - Argentine border. The Group consists of two formations; the Tilito Formation (27 – 23Ma), composed of high-K calc-alkaline andesite lavas and dacitic to rhyolitic ignimbrites, which have been intruded by basic to intermediate dykes; and the Escabroso Formation (21 – 18Ma), composed of medium-K, pyroxene bearing, calc-alkaline basaltic and andesitic lavas (Kay et al., 1987; Kay et al., 1991; Makshev et al., 1984; Martin et al., 1997). The Tilito Formation is thought to be derived from a long lived volcanic centre and the volcanic rocks have undergone significant hydrothermal alteration and mineralisation (Bissig et al., 2001; Litvak et al., 2007; Syracuse et al., 2010). The Tilito and Escabroso formations are separated by a major unconformity (Martin et al., 1995) which has been attributed to a period of deformation at ~20 Ma (Kay and Mpodozis, 2002).

During the production of the calc-alkaline Doña Ana Group at the arc front, the Las Máquinas basalts were being erupted in the back-arc region. These alkaline basalts have been K-Ar dated between 22.8 ± 1.1 Ma and 22.0 ± 0.8 Ma and their trace element geochemistry suggests they were erupted in an extensional setting with influence from the subducting slab (Kay et al., 1991; Litvak et al., 2005). The volcanic Las Trancas Formation, which outcrops in the Argentinean Precordillera and consists of andesitic to rhyolitic

210 proximal block-and-ash pyroclastic flow deposits, ignimbrites, tuffs and dacitic lava flows,
 211 has also been identified as coeval with the Tilito Formation (Poma et al., 2005).

212 The volcanic Cerro de las Tórtolas Formation also appears on either side of the current
 213 Chilean - Argentinean border (Fig. 1). These lavas were erupted during the middle Miocene
 214 and are primarily composed of amphibole bearing, medium- to high- K calc-alkaline
 215 andesites and dacites. Ramos et al. (1989) and Litvak et al. (2007) identify two separate
 216 sequences; an older (17 - 14 Ma) andesitic to basaltic andesitic lower section which appears
 217 to have been erupted through a normal thickness of crust (30 – 35 km) and a younger (13 –
 218 10 Ma) dacitic upper sequence.

219 The Infiernillo unit (18 – 15 Ma) is thought to be the subvolcanic equivalent of the Cerro de
 220 Las Tórtolas Formation and is composed of high-K calc-alkaline, shallow level, intermediate
 221 intrusives (Kay et al., 1987) (Fig. 2). A number of sub-volcanic outcrops identified in the
 222 Precordillera have been correlated with the Infiernillo Unit and are referred to as the
 223 Miocene Intrusives and Tertiary Intrusives (Cardó and Díaz, 1999; Cardó et al., 2007). The
 224 Miocene Intrusives which primarily consist of granitoids and have been dated between 22.4
 225 ± 0.1 and 21.2 ± 0.1 Ma (Llambias et al., 1990). Ages as young as 13.5 ± 7 Ma have been
 226 obtained for other deposits (JICA-MMAJ, 1999) and these have also been grouped into the
 227 Miocene Intrusives (Cardó et al., 2007). The Tertiary Intrusives consist of sub-volcanic
 228 andesites and dacites, and K-Ar dating has given ages of 18.3 ± 2.5 Ma and 17.5 ± 5 Ma
 229 (Cardó and Díaz, 1999; Leveratto, 1976), as well as a younger age of 8.8 ± 0.3 Ma (Wetten,
 230 2005).

231 The Late Miocene, Vacas Heladas Ignimbrites represent the last significant volcanic activity
 232 in the region with a reported K-Ar age of 6.0 ± 0.4 Ma (Ramos et al., 1989). These high-K

rhyolitic and dacitic tuffs lie unconformably over the Oligocene – Miocene sequences and have been correlated with the Vallecito Formation in Chile, which yields the same age (Bissig et al., 2001; Maksaev et al., 1984). These ignimbrites are isotopically enriched and contain the highest proportion of crustal components (e.g., Litvak et al., 2007).

4. The southern Central Andean basement

The basement present in the Principal and Frontal Cordillera's is primarily composed of Paleozoic marine sedimentary deposits and meta-sediments which have been intruded, and unconformably overlain by Late Paleozoic to Mesozoic plutonic complexes and volcanic deposits (Kay et al., 1989; Martin et al., 1999). In Chile, Late Paleozoic – Mesozoic plutonic complexes range in composition from gabbros to granites with two 'super-units' identified according to age: the Late Carboniferous – Early Permian, Elqui Complex and the Permian – Early Jurassic, Ingaguás Superunit (Mpodozis and Cornejo, 1988; Mpodozis and Kay, 1990, 1992; Nasi et al., 1990). The Colangüil Batholith is the age equivalent in Argentina (e.g., Llambias and Sato, 1990; Llambías and Sato, 1995; Sato et al., 2015). There are also extensive deposits of Permian - Early Jurassic silicic, volcanic rocks (e.g., the Choiyoi Group and the Pastos Blancos Group) (Martin et al., 1999; Nasi et al., 1985). All the aforementioned Late Paleozoic - Mesozoic plutonic and volcanic rocks are suggested to have formed in the late stages of Carboniferous to Early Permian subduction along the western margin of Gondwana, and in a more extensional tectonic setting after the cessation of subduction in the Early Permian (Martin et al., 1999; Mpodozis and Kay, 1992).

The basement in the Argentinean Precordillera is composed of Grenville-aged crust (ages between ~1300 and ~950 Ma that are contemporaneous with the North American Grenville province) overlain by Cambrian to Ordovician strata. Although no Grenville-aged basement is exposed at the surface its presence has been identified by various geochemical studies and through the presence of xenoliths and xenocrystic zircon grains in Miocene volcanic rocks (e.g., Abbruzzi et al., 1993; Jones et al., 2015; Kay et al., 1996). It has been suggested that the basement of the Precordillera is a rifted fragment of Laurentian crust which was accreted onto the western margin of Gondwana during the Ordovician (e.g., Astini et al., 1995; Kay et al., 1996; Thomas and Astini, 2003; Thomas et al., 2004), although the origin and the exact timing of rifting and accretion remains widely debated (e.g., Finney, 2007; Keller, 1999; Rapela et al., 1998).

5. Sample preparation and analytical methods

5.1 Sample collection

Representative samples (based on the published maps and formation descriptions of Cardó and Díaz (1999), Cardó et al. (2007), Emparan and Pineda (1999), Mpodozis and Cornejo (1988), Nasi et al. (1990), Pineda and Emparan (2006), Pineda and Calderón (2008)) were collected from each of the major intrusive/extrusive Late Cretaceous to Late Miocene arc formations (detailed in Section 3) present between 29 and 31 °S (Figs. 1 and 2). Due to the eastward migration and expansion of the magmatic arc activity during this time interval, the sample locations form an W – E transect across the Andean Cordillera from Chile into Argentina (Fig. 1). Late Cretaceous to Late Miocene plutonic and volcanic rocks in the southern Central Andes are typically evolved, but where possible mafic samples were collected in order to evaluate source compositions and processes. A number of Late

Paleozoic – Early Mesozoic basement samples were also collected in order to assess their potential role in the contamination of the Late Cretaceous to Late Miocene arc magmas.

5.2 U-Pb dating

In order to obtain zircon grains for U-Pb dating ~5 kg of each sample was crushed using a tungsten carbide jaw crusher. Zircons were then separated from 42 crushed samples using a combination of density and magnetic separation (Section 1, Supplementary Material).

Individual zircon grains were hand-picked under a binocular microscope and mounted in epoxy resin accompanied by zircon Geostandards 91500 and/or GJ-1. These epoxy mounts were then ground and polished to expose the interior of the zircons at the surface.

Prior to analysis individual zircon grains were imaged and characterised using a Philips XL30CP Scanning Electron Microscope (SEM) at the University of Edinburgh in order to determine the presence or absence of multiple growth phases, xenocrystic cores, inclusions, and cracks. Imaging was carried out in both secondary electron (SE) and backscatter electron (BSE) modes, and suitable, representative zircons and specific locations for analysis were identified. U-Th-Pb analysis of zircons was performed on a Cameca ims 1270 secondary ion mass spectrometer (SIMS) at the NERC Edinburgh Ion Microprobe Facility (EIMF) using analytical procedures similar to those described by Kelly et al. (2008). Full details of analytical methods, applied corrections and data reduction are outlined in the Supplementary Material. Subsequent to analysis all analysed zircons were imaged on a SEM in both cathodoluminescence (CL) and SE modes to check the exact position of analysis, and to ensure the absence of cracks and inclusions at the bottom of the analysis pits (Fig. 3). Data from any problematic analysis locations (i.e. cracks present) was rejected. A total of 313 successful U-Th-Pb analyses were made and in most cases at least 8 successful analyses

of separate zircon grains were made per sample. Multiple analyses (core and rim) were made on selected zircon grains in order to obtain information on growth history and inheritance (Fig. 3).

5.3 Ar-Ar dating

Due to the lack of magmatic zircon in some of the more basic to intermediate samples Ar-Ar dating of plagioclase was conducted on two samples (RJ1111 and AM0887). Plagioclase phenocrysts were separated from the crushed rock samples using similar mineral separation techniques to those used to separate zircon. Plagioclase crystals were hand-picked under a binocular microscope and sent to the Ar-Ar Research Laboratory at the Open University for analysis. Full details are presented in Section 3 of the Supplementary Material.

5.4 Whole-rock major, trace and rare earth element analysis

Sample blocks weighing ~50g were cleaned and trimmed of any weathered surfaces, veins and xenoliths. These blocks were then crushed into chips using a tungsten carbide jaw crusher. The chips were also checked to ensure they contained no signs of alteration, veins, xenocrystic and xenolithic material, and then powdered in a tungsten carbide TEMA mill to obtain fine, homogeneous powders for analysis by X-ray fluorescence spectrometry (XRF) and inductively-coupled plasma mass spectrometry (ICP-MS). Details are presented in Section 4 of the Supplementary Material.

XRF analyses were carried out in the School of GeoSciences, University of Edinburgh following the analytical methods outlined in Fitton et al. (1998) and Fitton and Godard (2004). Major, minor and selected trace element (TE) compositions of 56 samples were analysed on a Philips PW2404 wavelength-dispersive sequential X-ray spectrometer with a 4

322 kW Rh-anode end-window X-ray tube. Major element oxide totals were generally within
 323 $\pm 0.9\%$ of 100% and have been recalculated to a 100% volatile free basis. Based on the
 324 repeated analysis of an individual sample prepared and analysed five times the precision for
 325 the major element analysis is determined as always being $<1.1\%$ (1σ) (Table A4,
 326 Supplementary Material). The accuracy of the measurements, based on repeated analysis of
 327 standard BHVO-1 (basalt) compared to the published values, is $<3.5\%$ relative (1σ) for all
 328 major elements, apart from P_2O_5 where accuracy is 5.5% relative (1σ) (Table A2,
 329 Supplementary Material). Precision for the TE and REE concentrations determined by XRF
 330 analysis is $<4\%$ (1σ) apart from for Ni where the precision is much lower. This may be a
 331 result of the low concentrations of Ni present in the analysed sample (average = 2.7 ppm).
 332 Precision for Ni, based on the repeated analysis of BHVO-1 (117.5 ppm Ni) gave a precision
 333 of 0.5% (1σ) (Table A3, Supplementary Material). A full evaluation of the accuracy of the TE
 334 and REE analysis is presented in Table A3, Supplementary Material, but is generally
 335 determined to be better than 10% relative (1σ).

336 A subgroup of 39 samples representing each of the major volcanic and plutonic formations
 337 were selected for REE analysis via ICP-MS. Select samples were also analysed for U, Th, Pb
 338 and Hf concentrations. Sample powders were dissolved using a tri-acid digestion procedure
 339 and analysis was carried out on an Agilent 7500ce ICP-MS at the Scottish Universities
 340 Environmental Research Centre (SUERC), East Kilbride. Based on the repeated analysis of
 341 international standard BCR-2 the precision of the analysis is $<4\%$ (1σ) and the accuracy is <7
 342 $\%$ relative (1σ) for all elements apart from Pb, where precision and accuracy are much lower
 343 (7.3 and 30.9 $\%$ respectively) (Table A6, Supplementary Material). On this basis the use of Pb
 344 in the interpretations will be limited. A good agreement has been found between the TE and

REE concentrations produced by XRF and ICP-MS analysis (Figures A5 - A7, Supplementary Material). Therefore, select REE concentrations determined for certain samples by XRF analysis is included alongside the REE concentrations determined by ICP-MS.

6. Results

Detailed sample information, including a summary of the petrology of each formation/unit (Table A7), and full results are presented in the Supplementary Material.

6.1 Geochronological results

The results of U-Pb dating and Ar-Ar dating for individual samples are presented in Table 1. In order to obtain overall U-Pb ages for the Late Cretaceous – Late Miocene samples the data has been plotted on Tera-Wasserburg plots, where the U-Pb data is uncorrected for common Pb and the mixing line is anchored to the $^{207}\text{Pb}/^{206}\text{Pb}$ ratio for modern day common Pb (0.84) (Section 2, Supplementary Material). The overall U-Pb ages for these samples are given by the intercept on the Tera-Wasserburg plot and uncertainties are quoted at the 2σ or 95% confidence level. The overall U-Pb ages presented for the samples of the P-T basement are concordia ages or intercept ages with uncertainties quoted at the 2σ or 95% confidence level (Section 2, Supplementary Material). For the two samples dated using the Ar-Ar dating technique the age determinations are plateau ages with uncertainties quoted at the 2σ level (Figures A1 and A3, Supplementary Material). All of the plots and age calculations were made using computer program ISOPLOT v3.7 (Ludwig, 2008).

In the majority of cases the new U-Pb and Ar-Ar ages presented in this study confirm the previously reported age range of the sampled geological formations/units. However, in a

few instances the ages obtained by this study are at odds with the previously reported ages and the geological maps of the region; these differences are outlined below.

A number of dacitic and rhyolitic ignimbrites and lava flows which outcrop in the Valle del Cura region (Frontal Cordillera, Argentina) have previously produced Eocene K-Ar ages ranging between 44 ± 2 and 34 ± 1 Ma, and have been assigned to the Valle del Cura Formation (Limarino et al., 1999; Litvak and Poma, 2005). Samples of the Valle del Cura Formation collected as part of this study have produced Late Oligocene to Early Miocene ages, ranging between 24.3 and 17.1 Ma (Table 1). Oligocene to Early Miocene ages have also been reported for the Valle del Cura Formation by Winocur et al. (2015). These authors propose that the units previously identified as the Valle del Cura Formation are part of the Doña Ana Group. The U-Pb dating presented by this study supports this inference and some of the samples of the Valle del Cura Formation collected as part of this study have been assigned to the Doña Ana Group. Other samples thought to be the Valle del Cura Formation have been assigned to the Cerro de las Tórtolas Formation due to the younger ages obtained (17.1 Ma) (Table 1, Fig. 2).

A number of intrusive units which crop out in the Precordillera of Argentina have been mapped as Miocene Intrusives and Tertiary Intrusives and correlated with the Infiernillo Unit found on the Chilean side of the border (Cardó and Díaz, 1999; Cardó et al., 2007). However, the U-Pb ages obtained in this study, as well as geochemical evidence, suggest these intrusive bodies are not related. U-Pb ages of between 22.2 ± 0.2 and 20.4 ± 0.3 Ma were obtained for the Miocene Intrusives present in the Llanos del Molle (Llambias et al., 1990) and mapped by Cardó et al. (2007). These ages are significantly older than the ages reported for the Infiernillo Unit on the Chilean side of the boarder (18 – 15 Ma, (Kay et al.,

1987)). Conversely, much younger U-Pb ages (11.7 ± 0.2 to 9.4 ± 0.2 Ma) were obtained for the Tertiary Intrusives which outcrop in the Precordillera. Previously reported K-Ar ages for these sub-volcanic andesites and dacites range between 18.3 ± 2.5 Ma and 17.5 ± 5 Ma (Cardó and Díaz, 1999; Leveratto, 1976), perhaps explaining why these deposits have been linked with the Infiernillo Unit. The new U-Pb ages presented here are similar to the K-Ar age of 8.8 ± 0.3 Ma reported by Wetten (2005) for the same intrusive bodies, which this particular author refers to as the Cerro Bola Andesite. There is a variety of evidence to suggest that these intrusive bodies have been affected by hydrothermal alteration. On this basis we suggest that some of the K-Ar ages are likely to be unreliable and that the Tertiary Intrusives are Late Miocene in age and consequently distinct from the Infiernillo Unit.

6.2 Geochemical results

6.2.1 Major elements

The results of major oxide analysis are presented in Figures 4 and 5. The Late Cretaceous to Late Miocene magmatic rocks primarily have medium- to high- K, calc-alkaline compositions. The intrusive samples range from gabbroic to granitic in composition, with SiO_2 contents ranging between 50.9 and 71.3 wt.% (Fig. 4a). The extrusive samples range from basalts to rhyolites with SiO_2 contents ranging between 49.7 and 75.3 wt.% (Fig. 4b). All samples plot within the sub-alkaline field on plots of total alkalis versus silica with the exception of the Paleocene Río Frío Basalt, which is alkaline in composition (Fig. 4b). All the samples are relatively evolved with an average Mg# of 41 and Ni concentration of 11 ppm. The P-T basement rocks have medium- to high-K calc-alkaline to shoshonitic compositions and are more felsic than the Late Cretaceous to Late Miocene arc rocks, with SiO_2 contents ranging between 68.7 and 76.7 wt.% (Fig. 4).

Major elements, TiO_2 , Al_2O_3 , Fe_2O_3 , MgO , CaO , and to a lesser extent MnO display typical negative correlations with SiO_2 content (Fig. 5), whereas K_2O shows a positive correlation (Fig. 5). The plot of P_2O_5 versus SiO_2 content shows a convex trend with a general positive correlation between P_2O_5 and SiO_2 content until SiO_2 reaches ~ 63 wt.%, after which a negative correlation is observed (Fig. 5). These overall trends are consistent with fractional crystallisation (FC) processes, for example the increased crystallisation of apatite after ~ 63 wt.% SiO_2 . The alkali oxides, K_2O and Na_2O show the weakest correlations with SiO_2 (Fig. 5), suggesting that these elements may have been mobilised during alteration. The highest variation is observed in samples of the Cogotí Supergroup which shows a range of K_2O contents between 0.5 to 4.8% with a limited increase in SiO_2 content. Values for certain major element oxides, obtained for certain samples, also appear to sit away from the main data trends. For example, sample PC14 from the Tilito Formation appears to have lost all of its Na_2O and displays higher CaO and MnO contents (Fig. 5). This suggests leaching of Na, potentially from plagioclase, and replacement with carbonate minerals; this is confirmed by petrographic analysis (Figure A8, Supplementary Material). Therefore, some variation in the data away from the main trends displayed on the Harker diagrams may be the result of alteration and replacement processes.

6.2.2 Trace elements (TE) and rare earth elements (REE)

The results of trace- and rare earth- element analysis are presented in Figure 5 and 6. With the exception of the sample (RF17) of the Río Frío Basalts (Paleocene), all samples, including the Las Máquinas Basalts and those of the P-T basement, display typical subduction zone TE and REE signatures with enrichments in the large ion lithophile elements (LILE, e.g., Rb, K, Ba, Sr, Pb) and the light rare earth elements (LREE) relative to the high field strength

elements (HFSE, e.g., Nb, Zr, Ti, Y) and heavy rare earth elements (HREE) (Fig. 6). As evident in Figure 5, sample RF17 (Río Frío Basalts) has a distinct TE composition, with apparent enrichments in P, Nb and Zr. This sample is also alkaline in composition (Fig. 4b) and is clearly not co-genetic with other Paleocene arc formations (e.g., Cogotí Supergroup and Los Elquinos Formation), indicating that the Río Frío Basalts may have formed from a distinct mantle source.

The multi-element plots for all other samples exhibit prominent negative Nb anomalies and positive K and Pb anomalies (Fig. 6). With the exception of the most mafic sample (MQ8, Las Máquinas Basalts), all samples show negative Ti anomalies and depletions in HREE relative to N-MORB (Fig. 6). The Late Oligocene, Las Maquinas Basalts (MQ8) shows the least enrichment in the LILE, consistent with emplacement in a back-arc setting (e.g., Litvak and Poma, 2010). Samples of the Los Elquinos Formation (Paleocene), Tierras Blancas Caldera (Eocene) and Bocatoma Unit (Early Oligocene) display relatively limited enrichments in LILE, with the exception of Sr. These Paleocene – Early Oligocene samples, along with samples of the youngest (~13 – 6 Ma) arc formations (Upper Cerro de las Tórtolas Formation, Tertiary Intrusives and Vacas Heladas Ignimbrites), display positive Sr anomalies and limited negative Eu anomalies (Fig. 6). The youngest samples (~13 – 6 Ma) also have Sr contents which are significantly higher than the overall decreasing trend observed with increasing SiO₂ content (Fig. 5). In addition, these samples display relatively steeply dipping REE patterns with depletions in the HREE, suggesting a change in the petrogenesis of the youngest arc magmas erupted and emplaced in the southern Central Andes (Fig. 6).

7. Discussion

7.1 Temporal variations in the contamination of southern Central Andean arc magmas

It is clear from many of the TE plots (e.g., Figures 5b and 6) that there are significant variations in either the degree of melting or the composition of the source of the arc magmas, or in the level of interaction with the continental crust, over time. How the TE compositions have changed over time, due to what processes, and how this relates to the changing geodynamic setting of the southern Central Andean margin, is discussed below.

7.1.1 The Late Cretaceous to Eocene

Concentrations of incompatible, fluid-mobile (e.g., Ba, Pb, U) and fluid-immobile (e.g., Nb, Zr) elements, in the Late Cretaceous – Eocene samples of the Cogotí Supergroup, Los Elquinos Formation, Tierras Blancas Caldera and the Botacoma Unit, remain relatively constant with increasing differentiation (Fig. 5). There are limited correlations between certain TE ratios and SiO₂ content (Fig. 7) suggesting that these TE variations are not the result of FC. A number of lines of evidence support limited interaction of these arc magmas with the existing continental crust; no inherited zircon grains and cores are identified in these arc rocks (Table 1); ‘mantle-like’ $\delta^{18}\text{O}$ values have been obtained for zircons from these samples (Jones et al., 2015); and low $^{87}\text{Sr}/^{86}\text{Sr}$ isotope ratios have been reported for these the Late Cretaceous – Eocene magmatic belts (Parada et al., 1988). On this basis it is suggested that the observed enrichments in fluid-mobile, incompatible elements (e.g., LILE) and depletions in HFSE and HREE reflect processes occurring in the source region, rather than resulting from crustal contamination and/or differentiation processes.

Overall the fluid mobile/immobile TE ratios (e.g., Ba/Nb, U/Th) are highly variable for the Late Cretaceous – Eocene arc rocks (Fig. 7) suggesting that the source region has been variably influenced by slab-derived fluids. A general increase in these ratios is observed between the Late Cretaceous (~72 Ma) and the Eocene (~50 Ma) suggesting an increased

influence of slab-derived fluids on the arc magmas with time (Fig. 8). With an increase in fluid flux from the subducting slab an increase in the amount of partial melting occurring in the mantle wedge might be expected. An increase in certain element ratios (e.g., Nb/Zr, Nb/Yb) between the Late Cretaceous and the Late Eocene (Fig. 8) could be interpreted as an indication of a decrease in partial melting of the mantle over time. This is at odds with the evidence for an increase in fluid flux from the slab (e.g., increasing Ba/Nb and U/Th (Fig. 8)). Therefore, these element ratios are interpreted as representing an increase in the enrichment of the mantle wedge, either with subduction derived components (e.g., sediments) and/or due to an influx of asthenospheric mantle.

During this time interval magmatism was also occurring in a back-arc position, east of the main volcanic arc. These extension-related basalts (Río Frío Basalts 55.9 ± 1.9 Ma (Litvak and Page, 2002)) have a distinct composition to the magmas erupted in the main volcanic arc. These basalts exhibit high fluid immobile, incompatible TE ratios (e.g., Nb/Zr) and low fluid mobile, incompatible TE ratios (e.g., Ba/Nb), suggesting they represent small degree partial melts which received little influence from slab-derived fluids, as suggested by Litvak and Poma (2010)

7.1.2 The Late Oligocene to Early Miocene

After a period of reduced arc magmatism between the Mid Eocene and the Late Oligocene (Parada et al., 2007; Parada et al., 1988) the Doña Ana Group (Tilito and Escabroso Formations) was erupted at the arc front. The samples of the Tilito Formation (Lower Doña Ana Group) from closer to the trench, have quite distinct compositions from those collected farther to the east, despite their being of the same age (Late Oligocene). The more westerly rhyolitic ignimbrites (AM0844, AM0846 and AM0847) are highly evolved ($\text{SiO}_2 > 72$ wt.%),

504 have high concentrations of Nb (>18ppm) accounting for high Nb/Zr and Nb/Yb ratios
505 (Figures 8 and 9). The more easterly samples (ZN122 and Z27) are less evolved with
506 andesitic – dacitic compositions.

507 The presence of inherited zircon cores with P-T ages (ranging between 278.5 ± 2.9 Ma and
508 241 ± 2.7 Ma, (Table 1)) in the samples of the Tilito Formation from the Chilean side of the
509 margin, suggests bulk assimilation of the P-T basement (e.g., Beard et al., 2005). It has
510 previously been suggested that the contamination of the Late Oligocene – Early Miocene arc
511 magmas with P-T aged lower crust accounts for the relatively high $^{87}\text{Sr}/^{86}\text{Sr}$ ratios (0.705335)
512 of the Doña Ana Group (e.g., Kay and Abbruzzi, 1996). The range of inherited zircon ages
513 obtained by this study is within the range of U-Pb ages obtained for the Choiyoi Group and
514 Pastos Blancos Group, which comprise part of the basement stratigraphy. These basement
515 groups also appear adjacent to the Tilito Formation in outcrop and therefore it seems likely
516 that the magmas of the Tilito Formation have assimilated this crust. The similar geochemical
517 features (e.g., negative Eu, Ti and P anomalies, positive Y anomalies, high Nb/Zr ratios)
518 observed in samples of the P-T basement and the rhyolitic samples of the Tilito Formation
519 (Figures 4, 5, and 7) support this suggestion. No inherited zircon cores were found in the
520 more mafic samples erupted farther to the east, providing evidence for a more limited
521 interaction between the arc magmas and the basement farther away from the trench.

522 Coeval with the eruption of the Tilito Formation, the Las Máquinas Basalts were emplaced
523 to the east, on the Argentinean side of the margin. These basalts have high Nb/Zr (Fig. 9)
524 and Nb/U ratios and low fluid mobile/immobile incompatible element ratios (e.g., Ba/Nb
525 and Pb/Nb) (Fig. 7) suggesting a limited influence of fluids derived from the subducting slab
526 and initially relatively small degrees of partial melting. This is consistent with these

geological units representing back-arc volcanism (Kay and Abbruzzi, 1996; Kay et al., 1991; Litvak and Poma, 2010). On a plot of Nb/Yb vs. Th/Yb the Las Máquinas Basalt plots between the fields for E-MORB and OIB (Fig. 10) suggesting extraction of small degree melts from a relatively enriched mantle source. This might be expected for a region of the subcontinental mantle which has experienced less partial melting and melt extraction than the mantle situated beneath the main volcanic arc. These compositions are also similar to those of Holocene alkali basalts and trachy-basalts erupted in the back-arc region of the Southern Volcanic Zone (SVZ) (Jacques et al., 2013). These authors suggest that these back-arc basalts are formed from the melting of enriched Proterozoic subcontinental lithosphere.

The Miocene Intrusives, which consist of Early Miocene granitoids that crop out on the border between the Frontal Cordillera and the Precordillera, are highly enriched in incompatible elements such as Rb, Nb, Th, and Ce, which likely reflects their highly evolved nature. Ratios of fluid mobile/immobile incompatible element ratios are generally low, suggesting the limited influence of slab-derived fluids on the primary magmas (Figs. 7, 8 and 9). The U-Pb zircon ages presented here for the Miocene Intrusives (22.2 ± 0.23 to 20.43 ± 0.31 Ma) overlap with the ages obtained for the back-arc Las Máquinas Basalts (K/Ar dated between 22.8 ± 1.1 Ma to 22.0 ± 0.8 Ma (Kay et al., 1991; Litvak et al., 2005)). Like the Las Máquinas Basalts, the relatively high Nb/Zr ratios could be indicative of relatively small degree partial melting, which would be consistent with their generation relatively far away from the trench and therefore over a more dehydrated slab.

Geochemical modelling suggests that the compositions of the Miocene Intrusives can be generated from the composition of the Las Máquinas Basalts, by a combination of fractional crystallisation (FC), and assimilation and fractional crystallisation (AFC) processes involving

550 the P-T basement (Fig. 11), consistent with the presence of inherited zircon in sample
551 RJ11A14 (Table 1). It is difficult to separate the effects of FC from AFC processes, as in this
552 case the fractionating assemblage is virtually the same as the mineral assemblage found in
553 the P-T basement. Evidence from O and Hf isotopic composition of zircon (Jones et al., 2015)
554 suggests that the Miocene Intrusives have also interacted with an ancient, Grenville-aged
555 basement, which is present in the Precordillera. The modelling supports the involvement of
556 this ancient basement terrane, however it is apparent that the majority (~85%) of the
557 assimilated crust must be the P-T basement (Fig. 11). Overall, this suggests that these
558 granitoids, which are located farther away from the trench than the Las Máquinas Basalts,
559 have formed through the differentiation and interaction of these back-arc basaltic melts
560 with the pre-existing Andean crust.

561 The geochemical modelling also suggests that fractional crystallisation of these basaltic
562 melts can account for the compositions of the less evolved sequences of the Tilito
563 Formation, which outcrop further away from the trench (Tilito Formation – Argentina) (Fig.
564 11). The more evolved compositions closer to the trench (Tilito Formation – Chile) are more
565 difficult to generate via FC or AFC processes when using the Las Máquinas Basalts as a
566 starting composition. This suggests that the sequences for the Tilito Formation which are
567 closer to the Chilean trench may be the result of decoupled assimilation and fractional
568 crystallisation (i.e. FCA) (Cribb and Barton, 1996) and/or mixing processes involving the P-T
569 basement (Fig. 11), as suggested by the presence of inherited zircon cores. Alternatively
570 they may be derived from a different mantle source, which has received a greater influence
571 from subduction related components.

The extrusive rocks of the younger Escabroso Formation (Upper Doña Ana Group) and Cerro de Las Tórtolas Formation (Early Miocene) are generally more mafic than the Late Oligocene samples of the Tilito Formation and Miocene Intrusives (Fig. 4) and have lower Nb/Zr and Nb/Yb ratios, and higher fluid mobile/immobile incompatible element ratios (e.g., Ba/Nb and U/Nb) (Figs. 7, 8 and 9). This suggests a higher degree of partial melting of the mantle wedge due to an increase in fluids derived from the subducting slab, alongside more limited FC and assimilation of the Andean crust. During the Early Miocene (~18 Ma) the JFR began intersecting the Andean margin in this region leading to the initiation of the shallowing of the subducting slab (e.g., Yañez et al., 2002; Yañez et al., 2001). Therefore an increase in the influence of fluids derived from the subducting slab on the source of Early Miocene arc magmas might be expected.

These Early Miocene formations also lack any zircon inheritance (Table 1) providing further evidence for a reduction in the bulk assimilation of the Andean basement in comparison to the Late Oligocene, Tilito Formation and Miocene Intrusives. However, isotopic data still suggests the involvement of some radiogenic crustal components (e.g., Bissig et al., 2003; Jones et al., 2015; Kay and Abbruzzi, 1996; Kay et al., 1991).

7.1.3 The Mid to Late Miocene

During the Mid to Late Miocene the angle at which the Nazca plate was subducting shallowed and as a consequence arc magmatism migrated to the east. During this time interval the Tertiary Intrusives were emplaced in the eastern Frontal Cordillera and the Precordillera. These dacitic to trachydacitic units have relatively low Th, U and Rb concentrations, in addition to HREE depletions (Fig. 6). Kay and Abbruzzi (1996) also identified low Th, U and REE concentrations in the Precordilleran, Miocene arc magmatic

rocks and also found them to have the least radiogenic Sr ($^{87}\text{Sr}/^{86}\text{Sr} = 0.7032 - 0.7038$) and Pb ($^{206}\text{Pb}/^{204}\text{Pb} = 17.8 - 17.9$, $^{207}\text{Pb}/^{204}\text{Pb} = 15.48 - 15.49$, $^{208}\text{Pb}/^{204}\text{Pb} = 37.4 - 37.5$) isotopic signatures of all the Cenozoic arc magmatic rocks in the Pampean flat-slab segment. They attribute this to the interaction of the Miocene arc magmas with the distinct, Grenville-aged basement present in the Argentinean Precordillera; xenoliths from this basement also yield low Th, U and REE concentrations and unradiogenic Pb isotopic ratios (Abbruzzi et al., 1993). This suggestion is supported by the identification of inherited zircon cores of Proterozoic age in all Tertiary Intrusives samples analysed as part of this study (Table 1).

Kay and Abbruzzi (1996) suggested that the more radiogenic Pb isotopic composition of the Precordilleran Miocene arc magmas in comparison to the Grenvillian xenoliths ($^{206}\text{Pb}/^{204}\text{Pb} = 17.1 - 17.8$, $^{207}\text{Pb}/^{204}\text{Pb} = 15.42 - 15.49$, $^{208}\text{Pb}/^{204}\text{Pb} = 36.6 - 37.4$), requires the interaction of the magmas with an additional component, which has a Pb isotopic composition similar to that with which the Miocene arc magmas in the Frontal Cordillera have interacted. They proposed that this source of radiogenic Pb is derived from the sub-arc mantle wedge.

However, in addition to Proterozoic aged inherited cores, this study identified P-T inherited zircon cores in samples of the Tertiary Intrusives (Table 1), thus, suggesting these magmas have also interacted with crust of this age. Radiogenic Pb isotope values (e.g., $^{206}\text{Pb}/^{204}\text{Pb} = 18.44 - 18.56$, $^{207}\text{Pb}/^{204}\text{Pb} = 15.65 - 15.66$, $^{208}\text{Pb}/^{204}\text{Pb} = 38.38 - 38.39$ (Lucassen et al., 2002)) have been determined for the Late Palaeozoic Andean crust, and therefore we propose that the P-T basement may be the source of the radiogenic Pb.

In general as the subducting Nazca plate shallowed the volcanic front expanded and migrated to the east over the course of the Miocene. However, the youngest arc rocks in the region, the Vacas Heladas Ignimbrites occur in the Frontal Cordillera. During the same

618 time interval magmatism was occurring at the Pocho volcanic field in the Sierra de Córdoba,
619 situated directly to the east and 700 km away from the Chile trench. The Pocho volcanic
620 rocks are thought to be associated with the arrival of the shallowly dipping subducting slab
621 under this part of the South American continent (e.g., Kay and Gordillo, 1994). From this it
622 can be inferred that very little of the mantle wedge must have remained under the Frontal
623 Cordillera. Therefore, it is likely that the Vacas Heladas Ignimbrites represent small volume
624 lower crustal melts, generated due the influence of heat and fluids derived from the
625 subducting slab. These volcanic deposits have the highest fluid-immobile, incompatible TE
626 ratios (e.g., Nb/Zr and Nb/Yb (Fig. 8)) of the Mid – Late Miocene arc formations (i.e., 15 – 6
627 Ma), suggesting they represent small degrees of partial melting, consistent with the small
628 volumes of erupted magma. The high ratios of fluid-mobile/immobile incompatible TE (e.g.,
629 Ba/Nb, Pb/Ce) obtained from the Vacas Heladas Ignimbrites compared to the other Mid to
630 Late Miocene arc magmas, are also indicative of a high influence of slab-derived fluids on
631 these magmas. These melts have subsequently been contaminated with the Late Paleozoic –
632 Early Mesozoic basement and the older Cenozoic arc rocks, present in the upper crust. This
633 is consistent with TE signatures obtained for the Vacas Heladas Ignimbrites; relatively high
634 incompatible TE ratios (Figs. 7, 8, and 9) could be indicative of either relatively small degree
635 partial melts and/or assimilation of the continental crust. This is also consistent with isotopic
636 evidence; increasing $^{87}\text{Sr}/^{86}\text{Sr}$ ratios correlate with decreasing ϵNd values between the Late
637 Oligocene and the Late Miocene, with the highest $^{87}\text{Sr}/^{86}\text{Sr}$ ratios (0.7055) and lowest ϵNd
638 values (-2.0) reported for the Vacas Heladas Ignimbrites, suggesting an increase in crustal
639 contamination with time (Kay and Abbruzzi, 1996; Kay et al., 1991; Litvak et al., 2007).
640 Inherited zircon cores of P-T and Miocene age identify the crustal material being
641 incorporated into the melts (Table 1).

642 The Mid to Late Miocene arc magmatic rocks also have adakitic signatures (Fig. 12a).
643 Diagnostic geochemical features of adakites and their mode of formation remain
644 controversial (e.g., Castillo, 2012). Originally it was proposed that adakites formed from the
645 partial melting of young (<25 m.y.), basalt crust being subducted beneath volcanic arcs,
646 where garnet and amphibole are residual phases (Defant and Drummond, 1990; Kay, 1978).
647 Subsequently a number of other mechanisms of producing arc rocks with adakitic signatures
648 have been outlined, including partial melting of a mafic lower crust (e.g., Chung et al., 2003;
649 Kay et al., 2005; Kay et al., 1991), and high-pressure fractional crystallisation of hydrous
650 mafic arc magmas (e.g., Castillo et al., 1999; Macpherson et al., 2006; Rodríguez et al., 2007;
651 Rooney et al., 2011). To the south of the study area (~32 °S), Reich et al. (2003) propose that
652 melting of young, hotspot-derived rocks associated with the JFR has resulted in the adakitic
653 signatures of Late Miocene (~10 Ma) intrusions, on the basis of limited crustal thickness
654 (<35 km at 10 Ma) at these latitudes, combined with the non-adakitic signatures of more
655 recent arc rocks.

656 In the Pampean flat slab segment it is proposed that the adakitic signatures are the result of
657 the arc magmas equilibrating with high pressure mineral assemblages, including garnet, in
658 the lower crust (e.g., Bissig et al., 2003; Goss et al., 2011; Kay et al., 2005; Litvak et al.,
659 2007). During this time interval the thickness of the continental crust is suggested to have
660 increased to >45 km as a result of crustal shortening (e.g., Allmendinger et al., 1990; Kay et
661 al., 1991). This increase of crustal thickness could have also resulted in the high-pressure
662 fractional crystallisation of garnet or amphibole from the mafic arc magmas (e.g., Davidson
663 et al., 2007; Macpherson et al., 2006). However, the relatively flat trend displayed on a plot
664 of Dy/Yb against SiO₂ content (Fig. 12b) suggests these phases were not fractionated from

the melts and that they underwent gabbroic fractionation, which has a limited effect on the shape of REE patterns. This provides further evidence to suggest that the Mid to Late Miocene arc magmas were equilibrating with high pressure mineral assemblages in the lower crust. Overall, the development of adakitic signatures in the Mid to Late Miocene suggests that over the course of the Late Cretaceous to Late Miocene the arc magmas generated were equilibrating with different residual mineral assemblages, with a development from lower pressure assemblages (i.e. pyroxene) to higher pressure assemblages (i.e. garnet), likely reflecting the significant increase in crustal thickness over time.

8. The geodynamic evolution of the southern Central Andes

The new geochronological and geochemical data obtained by this study provides new evidence with which to refine the tectonic and geodynamic models of the Pampean flat-slab segment. An updated evolutionary model for the southern Central Andean margin between the Late Cretaceous and the Late Miocene is outlined below and in Figure 13.

8.1 The Late Cretaceous – Early Eocene (~75 – 51 Ma)

During the Late Cretaceous – Early Eocene (~75 – 51 Ma) the magmatic arc along the western margin of South America was somewhat different to the compressional Andean arc now in existence (Fig. 13a). The oblique angle of subduction and the low convergence rates between the Farallón and South American plates are thought to have caused extension along the margin (Charrier et al., 2007; Pardo Casas and Molnar, 1987; Somoza, 1998b). The Late Cretaceous to Early Eocene magmatic rocks, associated with extension, primarily

consist of north-south trending plutonic belts. Volcanic rocks associated with these extensive plutonic belts are scarce and may have been removed by erosion.

TE signatures suggest the Late Cretaceous to Early Eocene arc magmas, emplaced in the Principal and Frontal Cordillera's, formed in a subduction zone setting from the partial melting of a metasomatised mantle wedge, which has been variably influenced by slab-derived fluids. Evidence from boron isotopic compositions suggests these fluids were primarily derived from the dehydration of altered oceanic crust and serpentinite (Jones et al., 2014). TE signatures, such as low overall Nb/Zr and Nb/Yb (Figs. 7 and 8) suggests significant partial melting of the mantle wedge took place during this time period. Whole-rock rare earth element geochemistry (e.g., La/Yb ratios) suggests the Late Cretaceous to Early Eocene mantle-derived melts underwent equilibration with/fractional crystallisation of a gabbroic assemblage, suggesting migration of the arc magmas through a crust of normal thickness (~30 - 35 km). A lack of zircon inheritance, 'mantle-like' oxygen isotope values and juvenile initial ϵHf values obtained for magmatic zircon (Jones et al., 2015), and low initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratios reported for these plutonic belts (Parada et al., 1988), suggests minimal contamination by older continental crust. This combined evidence suggests that this time period represents a sustained period of upper crustal growth in the southern Central Andes (Fig. 13a).

8.2 The Early Eocene to Early Oligocene (~50 – 27 Ma)

This time period is characterised by a reduction in arc magmatism and a transition from the emplacement of primarily plutonic belts in the Principal Cordillera, to arc volcanism further away from the subduction zone trench in the Frontal Cordillera (Fig. 13b). During the Mid to Late Eocene granitoids and andesitic porphyries were emplaced in the Principal Cordillera,

709 along with a number of intrusions related to caldera formation. In the Frontal Cordillera
710 volcanic deposits were emplaced (e.g., the Botacoma Unit) and incompatible TE ratios (e.g.,
711 Ba/Nb, Nb/Zr) suggest these deposits were formed from small degree partial melting of the
712 mantle wedge, with less influence from slab-derived fluids, in comparison to the plutonic
713 belts present in the Principal Cordillera. The more limited influence of slab-derived fluids
714 may reflect the position of this part of the arc further away from the trench, over a more
715 dehydrated slab (Fig. 13b). An increase in the influence of crustally derived material on the
716 compositions of these arc magmas is also identified between the intrusions emplaced in the
717 Principal Cordillera, and the arc magmas erupted in the Frontal Cordillera. In particular, the
718 presence of inherited zircon suggests that these Frontal Cordillera arc magmas assimilated
719 Late Palaeozoic – Early Mesozoic basement.

720 The poor development of the magmatic arc from 50 to 27 Ma may be related to the low
721 convergence rates ($\sim 5 - 8$ cm/yr) and oblique angle of subduction (NE direction) operating
722 between the oceanic Farallón and the South American plate (e.g., Pardo Casas and Molnar,
723 1987; Somoza and Ghidella, 2012). The reduction in arc magmatism has previously been
724 linked with an earlier period of flat-slab subduction along the Central Andean margin (e.g.,
725 O'Driscoll et al., 2012). The apparent eastward migration of the arc during this time interval
726 supports the shallowing angle of subduction, however there is little other evidence to
727 support flat-slab subduction during this time interval. For example, La/Yb ratios suggest that
728 the ascending arc magmas were equilibrating with/fractionating a mineral assemblage
729 which reflects a continental crust of normal thickness ($\sim 30 - 35$ km), and that these melts
730 were not derived from the melting of the subducting slab, which might result from flat-slab
731 subduction (Gutscher et al., 2000a).

8.3 The Late Oligocene – Early Miocene (~26 – 20 Ma)

After the period of relative magmatic quiescence, this time interval is associated with a dramatic increase in magmatic activity and a broadening of the magmatic arc (Charrier et al., 2007 and references therein; Pilger, 1984). This has been related to a major change in plate configuration at ~25 Ma involving the break-up of the Farallón plate into the Cocos and Nazca plates (Lonsdale, 2005). This tectonic reconfiguration resulted in subduction becoming more normal to the margin (ENE direction) and convergence rates increasing from ~8 cm/yr to an average of ~15 cm/yr (Pardo Casas and Molnar, 1987; Somoza, 1998b; Somoza and Ghidella, 2012).

In the southern Central Andes, this time period is characterised by the eruption of the Tilito Formation (Lower Doña Ana Group) in the main Andean arc, and extension related magmatism in the back-arc region (Fig. 13c). The Tilito Formation (26.1 – 23.2 Ma) was erupted over a wide arc front, which is now situated in the Frontal Cordillera. An extensional regime operated to the east of the arc front, both during the late stages, and after the eruption of the Tilito Formation. This back-arc magmatism involved the eruption of the Las Máquinas Basalts (22.8 – 22.0 Ma (Kay et al., 1991; Litvak et al., 2005)) in the Frontal Cordillera, and the emplacement of high-K granitoids (Miocene Intrusives, 22.2 – 20.4 Ma) alongside dacitic to rhyolitic ignimbrites and lavas (Las Trancas Formation, 22.6 Ma), in the Argentinean Precordillera. Between ~23 and 21 Ma there is an apparent reduction in magmatism at the arc-front, with magmatic activity concentrated in the back-arc region.

TE signatures and the presence of inherited zircon grains/cores in the high- K, calc-alkaline rhyolites of the Tilito Formation erupted closest to the trench suggests the magmas bulk assimilated the Late Paleozoic – Early Mesozoic basement *en route* to the surface. The

generally more mafic (andesitic) units of the Tilito Formation, erupted further away from the trench, show evidence for a more limited interaction with the Andean basement. The interaction of ascending mantle-derived melts with the overlying Andean continental crust is generally higher in the Late Oligocene to Early Miocene, than is evident earlier (i.e., Late Cretaceous – Mid Eocene). This evidence suggests the Late Oligocene to Early Miocene represented a period of significant crustal reworking and growth of the upper Andean continental crust due to both arc-related, and extension-related magmatism.

8.4 Early – Mid Miocene (~19 – 14 Ma)

After the apparent reduction in arc magmatism between ~23 and 21 Ma, arc magmatism at the arc-front was reinitiated with the eruption of the basaltic andesite and andesite lavas of the Escabroso Formation (Upper Doña Ana Group) and the Cerro de las Tórtolas Formation. An eastward migration of the arc-front is observed with the majority of arc volcanism occurring on the now Argentinean side of the margin (Fig. 13d). The REE compositions of the Escabroso and Cerro de las Tórtolas Formations (lower) indicate the arc magmas migrated through a continental crust of normal thickness and that the Andean crust had not yet undergone significant tectonic shortening related to increased compression.

The combination of higher fluid-mobile/immobile incompatible TE ratios and lower fluid-immobile incompatible TE ratios obtained for the Escabroso and Cerro de las Tórtolas Formations are indicative of an increased influence of slab-derived fluids on the melt source region, and a higher degree of partial melting, in comparison to the Late Oligocene. This is supported by boron isotopic compositions and concentrations obtained from melt inclusions (Jones et al., 2014). During this time interval subduction of the JFR began along the Andean margin. The JFR has been associated with hydrated and serpentinised oceanic

778 lithosphere (Kopp et al., 2004), hence the subduction of this hydrated ridge may account for
779 observed increase in the influence of slab-derived fluids on the melt source region.

780 *8.5 Mid – Late Miocene (~13 – 6 Ma)*

781 During the Mid to Late Miocene the angle of the subducting Nazca plate shallowed, causing
782 the migration of arc magmatism to the east and an increase in compression along the
783 margin, resulting in the main phase of uplift of the Andean range (e.g., Gregory-Wodzicki,
784 2000; Kurtz et al., 1997). In the Pampean flat-slab segment, arc magmatism during this time
785 interval primarily consists of the eruption of trachyandesitic to dacitic lavas of the Upper
786 Cerro de las Tórtolas Formation in the Frontal Cordillera, and the emplacement of shallow
787 level, sub-volcanic andesites, dacites and trachydacites in the eastern Frontal Cordillera and
788 the Precordillera. Subsequent to this, the last significant magmatic activity in this region is
789 represented by the eruption of small volume, dacitic to rhyolitic ignimbrites, the Vacas
790 Heladas Ignimbrites, in the Frontal Cordillera (Fig. 13e).

791 Zircon inheritance and the isotopic compositions (Jones et al., 2015; Kay et al., 1991)
792 obtained for the Vacas Heladas Ignimbrites suggests the involvement of a Grenville-aged
793 basement, the Late Paleozoic – Early Mesozoic Andean crust, as well as Cenozoic crust in the
794 petrogenesis of these arc magmas. The interaction of these relatively young (~6 Ma) arc
795 magmas, erupted in the Frontal Cordillera, with a Grenville-aged basement supports a
796 number of structural models for the southern Central Andean margin (e.g., Gans et al.,
797 2011; Gilbert et al., 2006; Ramos et al., 2004). These models suggest the Grenville-aged
798 basement identified in the Argentinean Precordillera (e.g., Abbruzzi et al., 1993; Kay and
799 Orrell, 1996; Rapela et al., 2010), has under-thrust the Frontal Cordillera as a result of
800 crustal shortening.

A principal feature of the Mid to Late Miocene arc magmatic rocks is their adakitic signatures (Fig. 12). These have been interpreted as representing the melting and equilibration of arc magmas with a high pressure mineral assemblage, which includes garnet, in the lower crust. The occurrence of adakitic signatures in the Mid to Late Miocene is consistent with the timing of significant tectonic shortening in the region and the proposed timing of the main uplift of the Andean range (e.g., Gregory-Wodzicki, 2000; Kurtz et al., 1997; Vandervoort et al., 1995). This increase in crustal thickness has been linked to the increase in compression, in part due to the shallowing of the subducting slab (e.g., Jordan et al., 1983; Kay et al., 1991). The presence of adakitic signatures in the Tertiary Intrusives, emplaced in the Argentinean Precordillera, suggests the continental crust must have thickened to >50 km at this across-arc position (western Precordillera), as well as beneath the Frontal Cordillera.

9. Conclusions

The new age data and TE and REE compositions obtained for Late Cretaceous to Late Miocene arc magmatic rocks suggest progressive, yet variable contamination of the arc magmas over time. This study clearly demonstrates the link between the changing geodynamic setting in the southern Central Andes, specifically related to changes in the angle of the subducting slab and convergence angles and rates, and the compositions of the Late Cretaceous to Late Miocene arc magmas present in the Pampean flat-slab segment.

The TE geochemistry of the Late Cretaceous to Eocene arc rocks, combined with a lack of inherited zircon, provides evidence to suggest the Late Cretaceous to Late Eocene arc magmas had little interaction with the overlying Andean crust *en route* to the surface. This confirms previous evidence (e.g., Jones et al., 2015; Parada, 1990; Parada et al., 1988) and is

824 in keeping with the more extensional regime and thinner continental crust in existence
825 during this time period. The increased enrichment of arc magmas during this time interval is
826 proposed to be a result of the gradual enrichment of the mantle wedge due to the increased
827 influence of subducting components and/or the influx of asthenospheric mantle.

828 The TE and REE compositions of the Late Oligocene (~26 Ma) to Early Miocene (~17 Ma),
829 and Late Miocene (~6 Ma) arc magmatic rocks present in the Frontal Cordillera, combined
830 with the presence of P-T inherited zircon cores, provides evidence for the bulk assimilation
831 of the P-T basement by these arc magmas. The distinct TE signatures (specifically low Th, U
832 and REE concentrations) obtained for the Tertiary Intrusives (11.7 – 9.4 Ma), located in the
833 Argentinean Precordillera, combined with the presence of inherited zircon cores of
834 Proterozoic age, suggests these arc magmas have also interacted with the Grenville-aged
835 basement present in the Precordillera.

836 The progressive enrichment of arc magmas in incompatible TE between the Late Oligocene
837 (~26 Ma) and the Late Miocene (~6 Ma) is attributed to a combination of (1) the increased
838 influence of subducting components on the melt source region, and (2) increased
839 contamination of the arc magmas with existing continental crust *en route* to the surface.
840 Both of these processes are linked with the shallowing angle of the subducting Nazca plate,
841 the increased compression along the margin, and the consequent increase in crustal
842 thickness.

843 **Acknowledgements**

844 We are grateful to Nic Odling and Katarzyna Sokol for assistance in XRF analysis, and to
845 Valerie Olive for expertise and guidance in ICP-MS analysis. James Malley and Sarah

846 Sherlock are thanked for conducting the Ar-Ar dating, and Benjamin Heit, Dante Scatolon
847 and Eduardo Campos for help with fieldwork logistics. We would also like to express our
848 gratitude to Mike Hall and Robert McDonald for help with sample preparation and to Nicola
849 Cayzer for guidance in SEM imaging. Godfrey Fitton, Alan Hastie, Cees-Jan de Hoog, Simon
850 Harley and Jon Davidson are thanked for engaging discussions relating to the content of this
851 manuscript. This work was funded by a NERC CASE studentship (NE/G524128/1) and the
852 Derek and Maureen Moss Scholarship. SIMS analysis at the EIMF was supported by NERC
853 (IMF425/1010). Linda Kirstein acknowledges support from the Carnegie Trust for the
854 Universities of Scotland. The manuscript has benefited from thorough reviews from Pat
855 Castillo and an anonymous reviewer.

888 rocks (both intrusive and extrusive), and samples of the P-T basement.

889 Figure 10. Th/Yb vs. Nb/Yb discrimination diagram as defined by Pearce (2008). Values for N-
890 MORB, P-MORB, OIB and primitive mantle (PM) from Sun and McDonough (1989), for

891 GLOSS from Plank and Langmuir (1998) and upper continental crust (UCC) from Taylor and
892 McLennan (1995).

893 Figure 11. Geochemical modelling conducted using the FC-AFC-FCA modeler of Ersoy and
894 Helvacı (2010). The modelling uses the partition coefficients for intermediate melt
895 compositions and an 'r' value of 0.3 (i.e., 30 % assimilated material), as is supported by
896 evidence from zircon isotope data (Jones et al., 2015). The starting composition used is
897 sample MQ8 (Las Máquinas Basalts) and is the least evolved sample from the region with a
898 composition close to E-MORB (Fig. 10). The fractionating assemblage used to model the
899 orange FC trend is plagioclase (35 %), K-feldspar (15 %), magnetite (20 %), amphibole (5 %),
900 biotite (10 %), clinopyroxene (10 %) and olivine (5 %); consistent with the minerals present
901 in samples of the Las Máquinas Basalts and the more mafic samples for the Tilito Formation
902 which outcrop in Argentina (i.e., further away from the trench) (Table A7, Supplementary
903 Material). In this case increments represent 6% and crystallisation ends at 54%. The
904 fractionating assemblage used to model the green FC trend is plagioclase (30 %), K-feldspar
905 (15 %), magnetite (15 %), amphibole (15 %), biotite (13 %), clinopyroxene (5 %), olivine (5
906 %), apatite (1 %) and zircon (1 %); consistent with the minerals present in samples of the Las
907 Máquinas Basalts and Miocene Intrusives (Table A7, Supplementary Material). Increments
908 on the green FC, AFC, FCA and mixing lines represent 8% and crystallisation ends at 72%,
909 consistent with what might be expected for granitic (Miocene Intrusives) and rhyolitic rock
910 types (Tilito Formation – Chile). The composition of the Grenville-aged basement is the
911 average composition of xenoliths presented in Kay et al. (1996).

912 Figure 12. a) Sr/Y vs. Y (boundaries are from Richards and Kerrich (2007)), typically used for
913 distinguishing adakites as defined by Defant and Drummond (1990) and Drummond and
914 Defant (1990), and b) Dy/Yb vs. SiO₂ (wt.%) for Mid to Late Miocene samples from the
915 Central Andes. Data presented is from this study and from Bissig et al. (2003) and (Reich et
916 al. (2003)).

917 Figure 13. Schematic cross sections of the southern Central Andean margin at approximately
918 29 – 31°S, showing the geodynamic evolution of the margin from the Late Cretaceous (~75
919 Ma) (a) through to the Late Miocene (6 Ma) (e).

Table 1. The results of U-Pb and Ar-Ar dating and assigned geological unit (determined based on sample location, the new age determinations, and the results of whole rock geochemical analysis). The two sample ages which are displayed in italics and underlined are those obtained by Ar-Ar dating of plagioclase. Sample age calculations have been made using computer program ISOPLOT v3.7 (Ludwig, 2008). The age range ($^{206}\text{Pb}/^{238}\text{U}$ ages) of inherited zircon grains/cores are also presented where identified. The large uncertainty on the U-Pb age obtained for sample AM0890 reflects the limited number of zircon grains obtained from this sample (Supplementary Material). However, the U-Pb age is very similar to the Ar-Ar age produced for sample RJ1111 (61.2 ± 1.0 Ma), which is from the same formation (Los Elquinos Formation).
